

# VISUAL NETWORK ANALYSIS

WORK IN PROGRESS

Tommaso Venturini, Mathieu Jacomy, Debora Pereira  
Sciences Po Paris médialab

## INTRODUCTION

In the last few years, a spirit has been haunting our academic and popular culture — the spirit of networks. Throughout social as well as natural sciences, more and more phenomena have come to be conceived as networks. Telecommunication networks, neural networks, social networks, epigenetic networks, ecological and economic networks<sup>1</sup>, the very fabric of our existence seems to be made of lines and dots. More recently, the interest for graphs overflowed from science to popular culture and images of networks started to appear everywhere. They decorate buildings and objects; they are printed on t-shirts and furniture; they colonize the desktop of our computers and the walls of our airports. Networks have become the emblem of modernity, a way to show and tell our world's complexity. Our growing fascination for networks is not unjustified. Networks are powerful conceptual tools, encapsulating in a single object multiple affordances for computation (networks as graphs), visualization (networks as maps) and manipulation of data (networks as interfaces).

In the first place and to a large extent, the success of networks has to be credited to the amazing versatility of graph mathematics. From railways to information routing, from financial to communications flows, from ecosystems to organization management graphs have met countless applications. Graph computational formalism proved so effective that we started seeing networks everywhere and transforming everything into systems of discrete but interconnected items. It would be unfair, however, to reduce networks to their mathematical properties. Graph theory has been around in mathematics since Euler's walk on Königsberg's bridges<sup>2</sup>, but it is not until the end of the last century that networks acquired a multidisciplinary popularity. Graph computation is certainly powerful, but it is also very demanding and for many years its advantages remained the privilege of scholars with solid mathematical bases.

In the last few decades, however, networks acquired a new set of affordances and reached a larger audience, thanks to the growing availability of tools to *design* them. Drawn on paper or screen, networks become easier to handle and obtain properties that calculation cannot express. Far from being

---

<sup>1</sup> “The organic societies, like anthills and beehives, are metaphors that project the natural environment in the technological social space, as well as the structure of neurons and cells are models for understanding the networked world. In fact, networks naturally reflect the (dis) organization of the universe and nature. In a forest, eg., ecosystems are organized in network” (1996)

<sup>2</sup> *Solutio problematis ad geometriam situs pertinentis*, 1736.

merely aesthetic, the graphical representation of networks has an intrinsic hermeneutic value. Networks can become maps and be read as such.

Finally, the encounter with personal computing has recently turned networks into tools for data manipulation. Not only network-like visualizations are employed in a growing number of digital interfaces, but more and more specialized software has been designed to support the exploration of network data. Tools like Pajek ([vlado.fmf.uni-lj.si/pub/networks/pajek](http://vlado.fmf.uni-lj.si/pub/networks/pajek)), NetDraw ([sites.google.com/site/netdrawsoftware](http://sites.google.com/site/netdrawsoftware)), Ucinet ([www.analytictech.com/ucinet](http://www.analytictech.com/ucinet)), Guess ([graphexploration.cond.org](http://graphexploration.cond.org)) and more recently Gephi ([gephi.org](http://gephi.org)) have progressively smoothed out the difficulties of graph mathematics, turning a complex mathematical formalism in a more accessible point-and-click interface<sup>3</sup>.

Combining the computation power of graphs with the visual expressivity of maps and the interactivity of computer interface, networks accomplish the dream of Exploratory Data Analysis (Tukey, 1977): a navigation through data so fluid that zooming in a single data-point and out to a landscape of a million traces are just a click away<sup>4</sup>. No wonder that networks are popular!

The expansion of networks from graphs to maps and interfaces has been impetuous and reached distant regions of science and society. Yet the visualization of networks has less reflexivity and formalization than other ways to represent data, like geographical maps. Network enthusiasts design their visualizations as if an obvious visual grammar was supporting anyone's reading process – but it is not the case! We painfully lack the conceptual tools to think of the projection of graphs on the space of a screen or page. The very vocabulary we use has been borrowed from mathematics (e.g. cluster, structural equivalence...) and geography (e.g. centrality, bridging...) and needs to be adapted to the new visual paradigm. This paper means to contribute to such reflection and proposes a tentative framework for the visual analysis of networks.

Before we move to the enunciation of a visual grammar of networks, however, we would like to briefly discuss what has delayed so far this type of reflection. The reasons date back to the very foundation of graph mathematics. By solving the problem of Königsberg's bridges, Euler performed the most classical of mathematical operations. He abstracted the formal structure of the problem from its empirical features: he took a city and turned it into a table of number (see figure 1). In doing so, Euler laid the foundation of discrete mathematics at the cost of separating the idea of network from its physical materializations. His operation has been so successful that, for the following two centuries and a half, the reflection on networks was dominated by their structural properties, with little interest for practical

---

<sup>3</sup> A simple look at the URLs of the subsequent tools reveals the efforts deployed to make network-manipulation tools user-friendly and thereby available to a larger public

<sup>4</sup> By offering a tool for dataspace navigation, networks are also fulfilling the dream of Gabriel Tarde, a forgotten father of social thinking, who imagined that the development of statistics would have one day allowed to overcome the distinction between qualitative and quantitative methods and between micro and macro sociology.

applications. One of the consequences of such focus on structures (at the expenses of the actual contents of networks) has been that mathematicians never saw the interest of representing networks. For them, design a network was (and to some extent still is) perfectly useless.

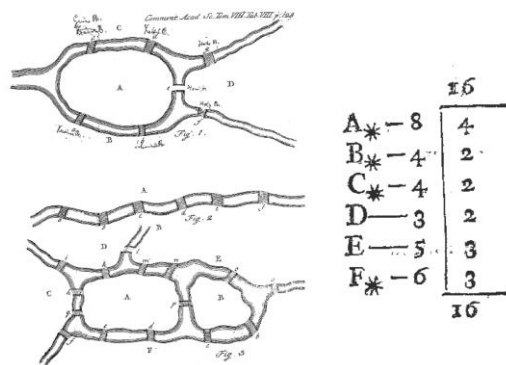

Figure 1 – Original figure and table from Euler's article.

The idea that it could be worth it drawing a network to see what it looks like came from a different tradition: the tradition of social networks analysis. Jacob Moreno, founder of this approach, was very explicit about the importance of visualization: "A process of charting has been devised by the sociometrists, the sociogram, which is more than merely a method of presentation. It is first of all a method of exploration. It makes possible the exploration of sociometric facts" (1953, pp. 95-96). Since Moreno and his followers were working on real networks constructed by the observation of actual social relations, it made sense to them to design networks. Identifying *visual patterns* became the equivalent of looking for social dynamics. In a seminal paper published on the New York Time in 1939, Moreno refers to network analysis as "a new geography" (see fig. 2). By drawing his sociograms, Moreno reconnected networks with their most ancient ancestor: the geometric figure, a set of points and line whose properties are meant to be explored by its visual representation. Graphs returned to be graphic.

## EMOTIONS MAPPED BY NEW GEOGRAPHY

Charts Seek to Portray the  
Psychological Currents of  
Human Relationships.

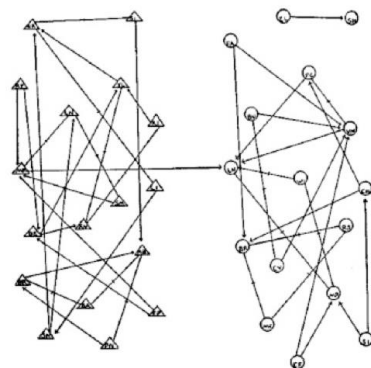

Figure 2 – Original figure and title from Moreno's article.

This of course, was only the beginning of the reflection on network visualization. Once you decide to draw a network as a set of dots and lines, you still have to decide which colors to use, which stroke, which style and, most crucially, which composition rules to follow. None of these questions is trivial and the story of how early analysts of social networks wrestled with their design is long and interesting. Unfortunately, we do not have here the space to tell such story (but see Freeman, 2010 for a remarkable account of it). For the paper, it will be enough to remark that, though crucial for the founders of social network analysis, the reflection on network design progressively lost its interest for their followers. Understandably fascinated by the parallel developments of graph mathematics, later social networks' analysts focused on statistics and progressively neglected networks design. In this paper, we draw on the reflection of Moreno and his early followers to discuss how the visualization of networks can be exploited for the study of social phenomena.

The next paragraph will introduce the three main visual variables (Bertin, 1967) mobilized by visual network analysis: the position of nodes, their size and their color (their hue to be more precise). We will briefly discuss the features of each of these variables and we will describe how they are employed to represent different characteristics of networks. After having set the theoretical basis of our approach, we will then propose an example of analysis in order to provide a practical guideline for visual network analysis.

## POSITION, SIZE, HUE AND THE MAIPIFICATION OF NETWORKS

Of the three variables used to graphically represent networks – position, size and hue – the first one is by far the most important. Like geographical maps, graphs are generally two-dimensional representations, but unlike maps they cannot rely on a predefined set of projection rules. In a geographical representation, the space is defined *a priori* by the way the horizontal and vertical axes are constructed. Points are projected on such pre-existing space according to a set of rules that assign them a pair of coordinates and thereby an univocal position. The same is true for any Cartesian coordinate system, but not for networks.

In networks, the position of nodes is rather determined by the effort to minimize visual cluttering. As soon as Moreno started drawing graphs, he discovered that some ways of positioning nodes could make his sociogram easier to read. He then enunciated the main rule still in use today to draw clearer networks: “the fewer the number of lines crossing, the better the sociogram” (1953, p.141). This criteria is still used to evaluate the quality of a layout (*Metrics for Graph Drawing Aesthetics*, Helen C. Purchase, 2002 <FETCH THIS REFERENCE>).

Easy to follow when working on a graph of a few dozen nodes and edges, Moreno's precept becomes impossible to implement directly on larger networks. Graphs with hundreds of nodes and edges cannot avoid thousands of line crossings: how to even know if moving a node increases or decreases the crossings? Since direct implementation of Moreno's precept is impossible, one can try an indirect approach: drawing closer the nodes that are connected minimizes the length of the edges and therefore

the possibility of crossings. But, even so, since each node is normally connected to several other nodes that are themselves connected to other nodes, minimizing the length of connection is far from being trivial.

The solution is a spatialization technique that came to be known as “force-directed placement algorithms”. A force-directed layout works following a physical analogy: nodes are given a repulsive force that drives apart, while edges act as springs binding the nodes that they connect. Once the algorithm is launched it changes the disposition of nodes until it reaches the equilibrium that guarantees the best balance of forces. Such equilibrium minimizes the number of line crossings and thereby maximizes the legibility of the graph. Fruchterman and Reingold, who proposed the first efficient force-directed algorithm in their famous paper *Graph Drawing by Force-directed Placement*, cite it as the second of their 5 aesthetic criteria. There is, however, a more interesting by-product of such visualization techniques: not only do force-directed algorithms minimize edge crossings, but they also give sense to the disposition of nodes in the space of the graph. Without spatialization, the distance between two nodes cannot be experienced the usual way: the mathematical distance in a graph is the number of edges that have to be ‘walked’ to go from a node to another. Still, this measure does not really resemble what we use to call a ‘distance’. Mathematicians define it as “non-Euclidian”. Two of its disturbing features are its discretization and the small-world phenomenon. Discretization means that you jump from one place (node) to another without any possibility to stop in the middle. The small-world phenomenon is experienced in practice when large networks have very short maximum distances (10 billion humans separated by a distance of only “6 degrees”).

When spatialization has projected the network as an image, on the contrary, you can experience the usual distance of the image (as in a map) as a proxy of the unusual distance inside the network: two nodes are visually close if they are directly connected (“Vertices connected by an edge should be drawn near each other”, Fruchterman Reingold) or connected to the same set of nodes (nodes with the exact same neighbors are mechanically destined to occupy the same position). Spatialization delivers an amazing result, it turns the discontinuous mathematics of graphs into a continuous space.

The other two visual variables employed in the visualization of networks – size and hue – are less crucial and easier to understand. According to Bertin (1967) the main difference between these two variables is that while size is adapted to represent ordinal values (comparing to elements, it is possible to say which one is bigger and how bigger it is), hue is not. Following such difference, in designing networks the size of the nodes is generally used to designate qualitative values (such as the importance of the nodes or strength of the connections), while the hue tend to be used to distinguish different categories of elements.

## AN EXAMPLE OF VISUAL NETWORK ANALYSIS

In this section we will provide some guidelines for visual network analysis by drawing on a practical example. Our case study is a network of websites and hyperlinks related to the 2012 United Nations Conference on Sustainable Development of Rio de Janeiro (aka Rio+20)<sup>5</sup>

We propose a series of steps that draw an analytical frame for visual network analysis. Each step of this method we will be discussed by a) introducing the conceptual principle employed to read the network; b) exemplifying the application of the principle on our case study; c) providing a possible interpretation of the patterns observed on the network. When necessary the analysis will be preceded by a description of the technical operations performed on the network.

The steps we will present are in the following order:

- Visualizing node positions
  - How to give a position to nodes
  - How to interpret variations of density
  - How to interpret the size and density of clusters
  - How to detect centers and bridges
- Visualizing node sizes
  - How to give a size to nodes
  - How to read the hierarchy of connectivity
- Visualizing node colors
  - How to apply a color to nodes
  - How to read the distribution of colored categories

## VISUALIZING NODE POSITIONS

### HOW TO GIVE A POSITION TO NODES

Before we can look at the image of the network, we have to produce it. This process we summarized as “spatialization” implies to perform a number of actions and taking a number of choices. In the previous paragraphs we introduced the three visual variables mobilized by visual network analysis. Now it is time to apply them on a practical case. The distribution of nodes in space is the first (and most important)

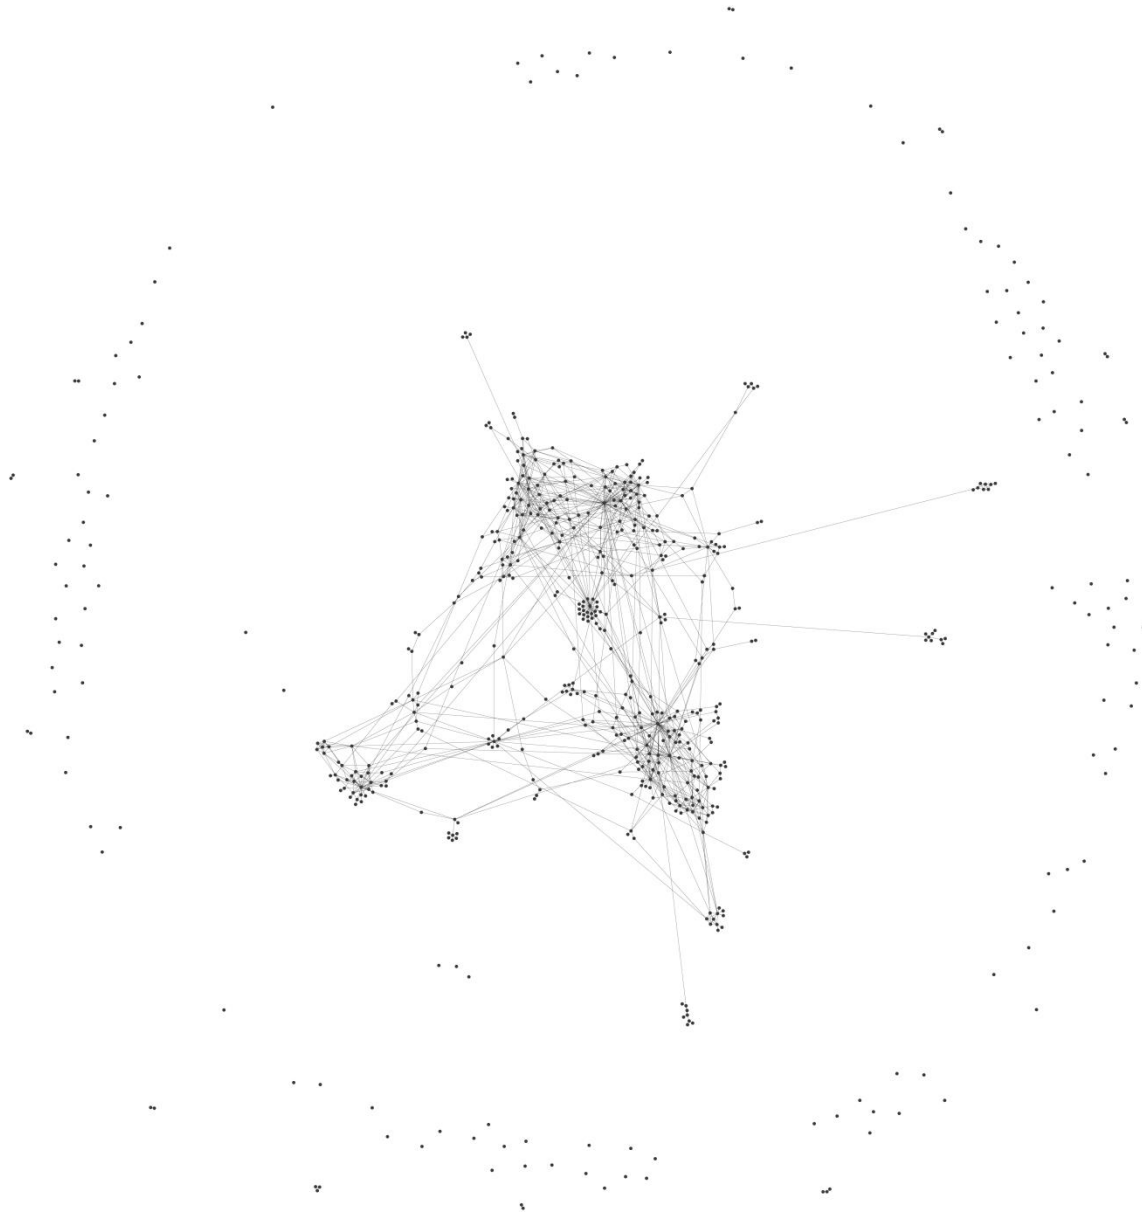

---

<sup>5</sup> « ‘Rio+20’ is the short name for the United Nations Conference on Sustainable Development which took place in Rio de Janeiro, Brazil in June 2012 – twenty years after the landmark 1992 Earth Summit in Rio. At the Rio+20 Conference, world leaders, along with thousands of participants from the private sector, NGOs and other groups, came together to shape how we can reduce poverty, advance social equity and ensure environmental protection on an ever more crowded planet» (<http://www.un.org/en/sustainablefuture/about.shtml>).

The websites that compose the corpus that we will analyze have been selected according to two criteria:

1. if they are issued by organizations and groups active on environmental issues;
2. if they contain contents specifically related to Rio+20 or if they authors were present and active in the Conference.

technical operation. Figure 1 shows the result of a force-driven layout obtained with the Gephi using the algorithm ForceAtlas2 (Jacomy et al., 2014) (LinLog mode, scaling 0.35, gravity 0.2, prevent overlap).

*Figure 3 – Network after the spatialization. The main component is the most interesting part. The disconnected nodes form the ring (size and colors have not been modified).*

## HOW TO INTERPRET VARIATIONS OF DENSITY

### READING PRINCIPLE

In most networks, spatialization reveals regions where numerous nodes are assembled and regions that are empty or almost. These differences of density (determined by the uneven distribution of links between nodes) are revealed by the force-directed algorithm like different light exposures are revealed by chemical agents in photography. Spatialization generates visual patterns that translate the mathematical properties of the network. This translation is not free from distortions: some properties are visible while others are not. Some of the things that can be observed are meaningful, others are not. For example, the absolute position of nodes and clusters (at the top or bottom, left or right of the image) is arbitrary. What matters is the *relative* position of nodes, their agglomeration and their separation. Clustering matters.

To be sure, clusters could be detected in other ways. Andreas Noack (2009), in particular, has shown that the mathematical mechanism of force-vectors corresponds to the computation of the clusters by modularity, a technique often used to detect communities in networks (Newman, 2006). Mathematical clustering however imposes a dissection of the network that is often too clear-cut. The advantage of visual techniques discussed in this article is that their fuzziness allows negotiating the frontiers of clusters. These frontiers are naturally blurred, since clusters are not exclusive categories, but shades of density. Clusters may have clear boundaries, like cliffs separating a plateau from the valley, but most of the time their borders are gradual as the slopes of a mountain. The fuzziness of clusters' frontiers, by the way, is no obstacle to their recognition: a mountain is easy to see even if it is impossible to say exactly where it starts and ends.

What is important is to be able to distinguish the clusters and identify the empty zones between them. These zones are called "structural holes". The larger these holes, the more they denote the absence of connection between clusters. In dense graphs (such as those designed by hyperlinks' web or scientometrics networks), such absence is particularly significant and can be interpreted as a symptom of opposition <FINDING A REFERENCE WOULD BE NICE>. Finally, we can remark that large clusters are often composed by smaller (and less distinct) sub-clusters. If large structural holes can be read as oppositions, smaller holes among sub-clusters may denote distinctions without opposition.

We can then summarize the reading principle of the first step by four questions:

- Which are the main clusters?
- Which are the main structural holes that separate them?
- Which are the sub-clusters within each cluster?
- Which are the smaller structural holes separating them?

#### *APPLICATION TO RIO+20*

**Which are the main clusters?** In our example network it is easy to identify three main clusters at the top (A), at the bottom right (B) and at the bottom left (C). The clusters A and B are the largest and the easiest to identify. The cluster C is smaller and does not contain more nodes than the plurality of smaller sub-clusters scattered through the graph. The cluster C, however, is clearly distinguished from A and B and occupies *its own space*. This is why we count it as one of the main cluster of the network. The

triangular shape of our network is thus the result of the three main clusters *pulling in three different directions*.

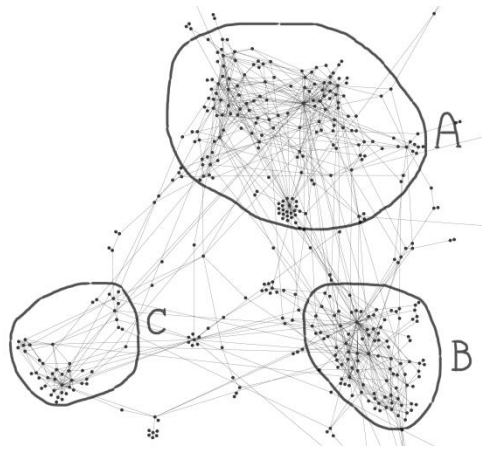

Figure 4 – Three main clusters (A-C)

**Which are the sub-clusters?** It is easier to distinguish the sub-clusters in the clusters A and B than in the cluster C that is significantly more compact. In A, we have identified two main sub-clusters a1 and a2 and three smaller groups of nodes. In C, we have identified three sub-clusters. In B, we decided not to separate any sub-clusters.

In the identification of the sub-clusters, there is always a part of subjectivity. Some sub-clusters are pretty evident (a1, a2 and c1), but most are not. Sub-clusters by definition smaller and less clear-cut than the main clusters and this can raise doubts on their existence: does c3 contains enough nodes to be interesting? Is a3 really separated from a1? We can leave these questions open for the moment. So far, the sub-clusters are only suggested to provide insights for the analysis.

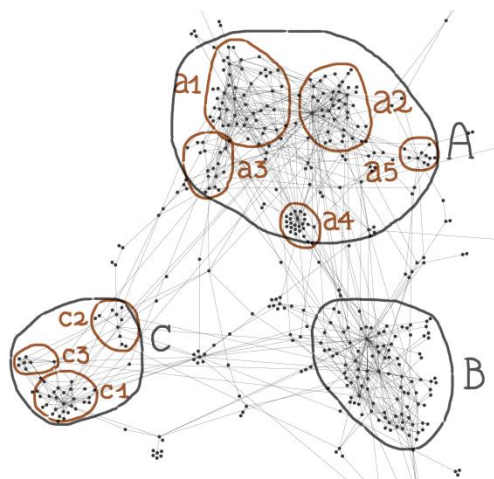

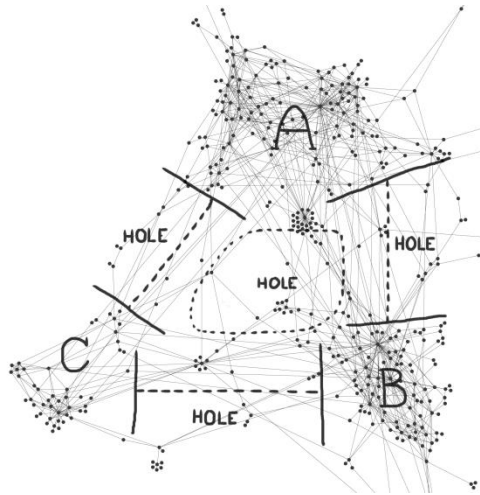

Figure 5 – Sub-clusters of A, B and C

**Which are the main structural holes?** In our network, there are four main structural holes: one at the center of the graph and three more separating the main cluster two by two. The cluster C is more isolated than the other two. The structural holes are evident in this network: the absence of links between main clusters is radical and demands to be explained.

*Figure 6 – Structural holes separating A, B and C*

Besides A, B and C, ten smaller clusters occupy different positions. These clusters can be divided in two groups: (1) The intermediary clusters M, E, F and L located among the main clusters. (2) The peripheral clusters K, G, I, D, J and H pushed towards the margins of the graph by the scarcity of edges that connects them to the three main clusters (some of them are so detached from the graph that we are led to consider the possibility of excluding them from the corpus).

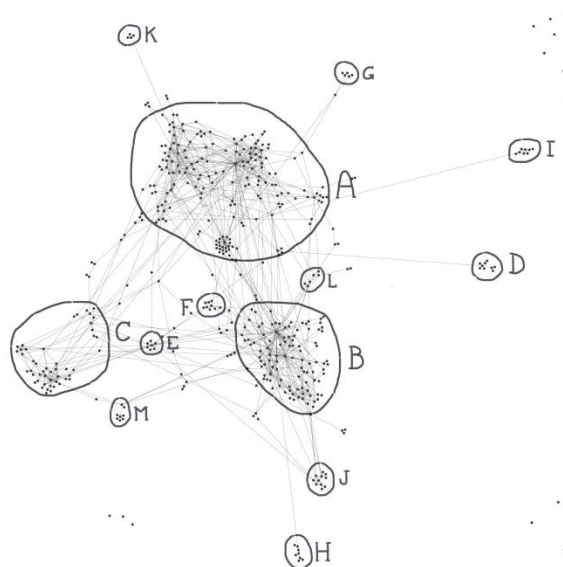

Figure 7 – Three main clusters (A-C) and ten smaller clusters (D to M)

### INTERPRETATION

After having spotted the clusters and sub-clusters of our network, we can try to make sense of them. The crucial aim of this phase is to find a suitable ‘collective name’ for each group of nodes. This is done by examining the nodes each cluster and trying to find what they have in common (at least what most of them have in common). Clearly some knowledge of the websites and their contents is necessary to discover their similarities and that why visual network analysis should always be accompanied by some form of qualitative enquiry. In our case all the websites have been visited and manually analyzed at the moment of constituting the corpus. The interpretation we will provide is therefore based on the knowledge accumulated during the constitution of the corpus. Making sense of clusters is important at this stage since we will intensively refer to them in the next sections. Clusters are the main landmarks of the reading process. The following table allows comparing the identity of the three main clusters:

Cluster	Remarkable features	Actors	Contents
A	Most heterogeneous cluster Few authorities Divided into 5 sub-clusters	Social movements, environmental and human rights NGOs (mostly in Brazil). Main sites: <a href="#">MST</a> , <a href="#">MAB</a> , <a href="#">Via Campesina</a> , <a href="#">CPT</a> , <a href="#">Racismo Ambiental</a> , <a href="#">Cândido Neto</a> , <a href="#">Telma Monteiro</a> , <a href="#">Ecodebate</a> , <a href="#">Xingu Vivo</a> , <a href="#">Cúpula dos Povos</a> , <a href="#">Greenpeace</a> , <a href="#">Isa</a> , <a href="#">International Rivers</a> , <a href="#">Fórum Br163</a> , <a href="#">Fórum Carajás</a> , <a href="#">Ingá</a> , <a href="#">Rainforest</a> , <a href="#">Governo do Brasil</a> .	Manifestations and social conflicts, indigenous issues, oppositions to dams, cultural events, courses agro-ecology, environmental education, forest management, event Peoples Summit.
B	Most homogeneous cluster Three dominant authorities Has no sub-cluster	UN-related agencies and NGOs working with the concepts of green economy and sustainable development. Main sites: <a href="#">ONU</a> , official <a href="#">Rio+20</a> , <a href="#">Unep</a> .	Reports on conferences and debates proposed by the United Nations. Repeated terms: alternative energy, clean water and air, bio, carbon sequestration, bio-solutions, green IT.
C	Divided into 3 sub-clusters	NGOs for the preservation of forests, indigenous movements and scientific groups who advocate global warming as caused by humans. Main sites: <a href="#">Real Climate</a> , <a href="#">Mongabay</a> , <a href="#">Indigenize</a> , <a href="#">Davi Suzuki</a>	Scientific terms, longer texts, campaigns and appeals for donation.

This characterization gives an empirical grasp on each clusters’ identity. A short analysis of each cluster is provided in appendice A. For more clarity, we propose a short title for each cluster to help you make sense of them.

- Cluster A: NGOs and Social Movements
  - Sub-cluster a1: Marxist Eco-socialism
  - Sub-cluster a2: Environmental Politics
  - Sub-cluster a3: Xingu Vivo movement
  - Sub-cluster a4: People's Summit
  - Sub-cluster a5: Brazilian Government

- Cluster B: International institutions
- Cluster C: Environmental and climate NGOs
  - Sub-cluster c1: Scientific Websites
  - Sub-cluster c2: Mongabay
  - Sub-cluster c3: Ecological Internet

In general, the main clusters A, B and C form three coherent ensembles of websites. Despite internal differences exist, the websites in each of the main clusters are connected by hyperlinks because they share analogous interests and worries and a similar language. These specificities are also the reason of the separation between the three clusters. The NGOs in A “NGOs and Social Movements” and the institutions in B “International Institutions” differ on every aspect: movements (A) VS. establishment (B); protest (A) VS. policy-making (B); mobilization (A) VS. planning (B). The institutions in B are also strongly opposed to the NGOs in C “Environmental and Climate NGOs” because of a deep difference in their values that opposes a pragmatic conception of modern societies and economies (B) to a radical questioning of the place of humankind in the world (C). Finally, the websites in C and A are separated by the object they defend: social groups and communities for A and environment and ecosystems for C. A and C also employ different forms of engagement: the rationality of scientific knowledge and distant donation of money (C) against the emotions of social movements and first person participation (A). These differences explain why there are few bridges between our three main clusters. The actors tend not to link each other, because of their ideological and practical opposition. They are more than different thematic clusters, they are opposed communities of interest.

## HOW TO INTERPRET THE SIZE AND DENSITY OF CLUSTERS

### *READING PRINCIPLE*

Network clusters have two main properties that we can observe separately: size and density. Making sense of these properties is crucial to understand the balance of forces in the network.

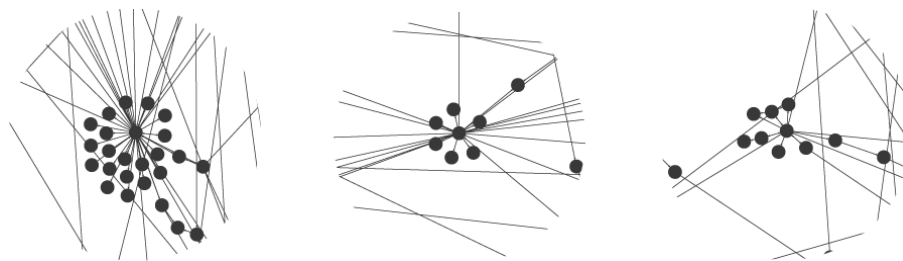

The size of clusters is defined as the number of nodes they contain. The biggest clusters are the most visible on the Web and it is interesting to investigate offline counterparts of such online significance. The Web is always a deforming prism. Minorities are sometime over-represented in online debate and some groups exist almost exclusively in the cyberspace. It is often relevant to compare the size of clusters on the Web to the presence of these actors in other public spaces (newspapers, institutions...).

The density of a cluster measures its cohesion. Clusters are tight when they contain many edges and loose when few edges connect their nodes. In the case of the Web, a high number of in-cluster links may denote the activity of a community: the actors know and acknowledge each other through their citations. A low density is also interesting. It may denote that the nodes do not know their neighbors or actively disregard them (because of competition or controversy). In low-density clusters, it is not the connections among their members that keeps them together, but the stronger separation with the rest of the network that *digs a ditch* of structural holes around them.

### *APPLICATION TO RIO+20*

The three main clusters count several dozens of nodes. Among them, A is the biggest and C the smallest. All the other clusters are definitely smaller with less than a dozen nodes.

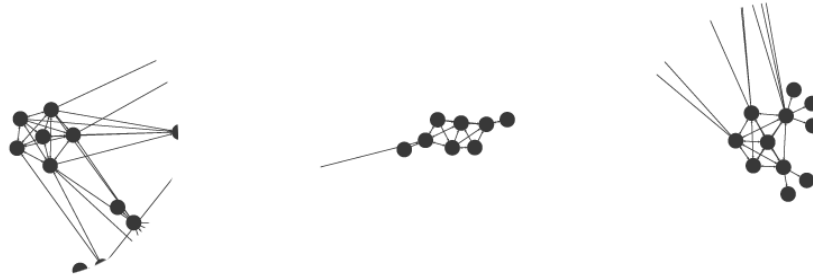

As for the density, B is the only among main clusters that is relatively dense. A and C are more spread out and clearly separated in smaller and denser sub-clusters (which appears to be more interesting than they larger parents). Cluster A is largely defined by a1 “Marxist Eco-socialism” and a2 “Environmental Politics”. These two sub-clusters are large and dense and contain most of the nodes of A. a3 “Xingu Vivo Movement” and a5 “Brazilian Government”, on the contrary, are scarcely dense and are distinguished from a1 and a2 only by their separated position. a4 “People's Summit” is special case because of its star structure (see fig. 8).

*Figure 8 – Star structures: the sub-cluster a4 and the smaller clusters E and F*

Similar little stars appears everywhere in the network (see fig. 8). They all are characterized by a central point surrounded by nodes that are only connected to the center but not among them. This is one case where visual network analysis can be misleading: though they look compact, the stars are not particularly dense from a mathematical point of view. In the case of the Web, we will interpret these patterns as the symptom of the activity of an authority or a hub (more on this later on) and not as the sign of a communitarian activity. It is therefore important to distinguish stars from clusters: though they may look equally dense, they are produced by very different mechanisms.

Cluster C contains a larger sub-cluster c1 “Scientific Websites”, a very sparse cluster c2 “Mongabay” and another special case c3 “Ecological Internet” that appears to be a clique. Cliques are groups of nodes that are all connected to each other. It is rare to observe large cliques in natural networks, but it is possible to find small ones (with less than ten nodes). Quasi-cliques are similar structures where *almost* all the nodes are connected (see fig. 9). Cliques and quasi-cliques have no center, even if some nodes may appear more central than the others on the image (if all nodes are connected, no node is more connected than the others).

*Figure 9 – Clique of the sub-cluster c3 and quasi-cliques of the clusters I and J*

### *INTERPRETATION*

Cluster A “NGOs and Social Movements” is the largest of our network and this is probably due to the fact that it corresponds to an active community. The “occupation of the Web” is an important issue for activists, both to assure their internal communication and to win the support of public opinion. The phenomenon of minorities’ over-representation may also be at play and this specific community may be particularly visible on the web. Cluster C “Environmental and Climate NGOs” is also composed predominantly by NGOs and associations, but its lesser size may indicate a smaller or less active community. Finally, the cluster B “International Institutions” is mainly composed of the numerous institutions gathered around the site of the United Nations (which explains the absence of sub-clusters). The links between institutions are often the simple mark of formal partnership. The size and shape of larger clusters seem therefore to be consistent with the different types of social organizations present in our network. The same can be said for the sub-clusters, which correspond to the divisions among the different types of associative groups present in A and C.

In the sub-cluster a1 “Marxist Eco-socialism”, a lot of information is circulated and discussed. This activity creates many links among the actors explaining the relatively high density. Blogs in particular, play a central role in this group of sites (more on this later). The sub-cluster a2 “Environmental Politics” displays a similarly intense communitarian activity (which explains the high number of links), but has a different thematic focus and is composed of a different type of actors, mostly NGOs. The separation between a1 and a2 may be in part explained by the fact that blogs tend to cite other blogs while NGOs prefer citing other NGOs. Though permeable, these two spheres remain relatively separated.

The sub-cluster a4 “People’s Summit” has the form of a star which can be explained by the fact that the social ecology scheme of the management of nature is well articulated, though it does not have the strengths nor the excessively referenced informational authorities. At the center of cluster C, the sub-cluster c1 “Scientific Websites” gathers an active and connected community. c2 “Mongabay” and c3 “Ecological Internet” represent two smaller groups of different types of actors (most NGOs) that though referring to the scientific blogs, are not confused with them. The clique structure of the c3 sub-cluster (experts in forest preservation, ecosystems and indigenous peoples) is explained by the fact that, with the exception of the sites Peoples Issues and New Earth Rising, all other sites mirror the content of the website Ecological Internet. Knowing the clique structure reinforces each actor notably in the search engine visibility, it would be interesting to investigate whether this strategy is deliberate.

## HOW TO DETECT CENTERS AND BRIDGES

### *READING PRINCIPLE*

Now that we have identified the clusters, we can use them as landmarks to analyze two remarkable positions in spatialized networks: centers and bridges.

Centrality can be global (referred to the whole network) or local (referred to a single cluster). These two types of centrality are different. While the elements that are globally central are pulled in this position by the fact of being evenly linked to all the regions of the network, the element that are locally central tend to be linked predominantly within one cluster. Central positions (local or global) can be occupied by single nodes or by (sub-)clusters. In many cases, the center of the network (or the center of a large cluster composed by several sub-cluster) is just empty.

Bridges, on the other hand, are nodes or clusters that have connections with several clusters (two or more, but not all the clusters of the network). Bridges can be located outside the clusters they connect, if their connections are evenly distributed among them, or they can be located within one of the clusters, if they are more connected to it than to the others.

The following questions may help to identify systematically central and bridging elements:

- Which nodes or clusters (if any) are located in the center of the network?
- Which nodes or sub-clusters (if any) are located in the center of each cluster?
- Which nodes (if any) are located in the center of each sub-cluster?
- Which nodes or clusters (if any) are located among the main clusters?
- Which nodes (if any) are located among the main sub-clusters?

### *APPLICATION TO RIO+20*

Six nodes have been identified as centers of clusters and sub-clusters. Nature.com is the only node occupying the center of our network and the only node to connect the three main clusters. UN.org the website of the United Nations, is at the center of the cluster B. CupulaDosPovos.org.br is at the center of the sub-cluster a4 “People’s Summit” and RealClimate.org is at the center of c1 “Scientific Websites”. Finally, two nodes are central in smaller clusters IUCNWorldConservationCongress.org for E and Demilitarize.org for F. The presence of many edges around each of these nodes has helped us to detect their centrality.

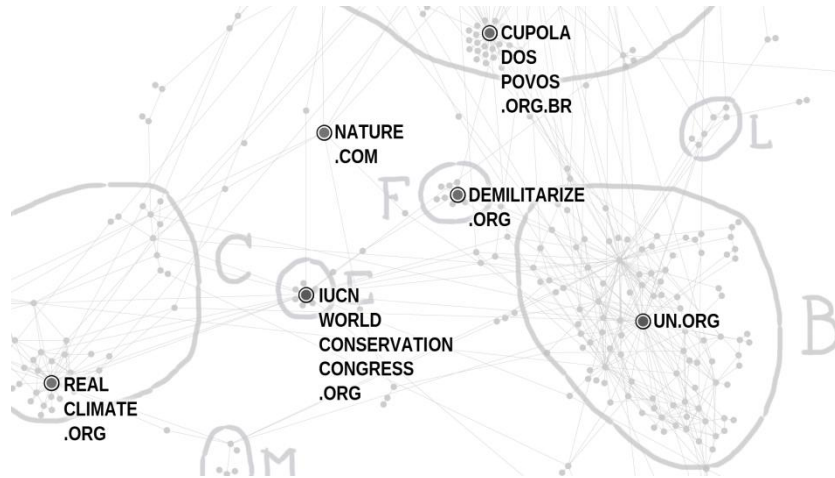

Figure 10 – Nodes in central position in the network or in their cluster

Three clusters and seven nodes are in bridge position. The clusters are the easiest to identify: E and F are located between B and C and L is located between A and B. Seven nodes are in a position to bridge between two clusters. Three nodes are simply “stretched” between two clusters: GlobalVoicesOnline.com (A and C), NoGreenEconomy.org (A and B) and EffetsDeTerre.fr (B and C). Care2.com and IndianCountryTodayMediaNetwork.com *together* form a (3 links-long) bridge between A and C. Finally, Bndes.gov.br is an “internal” bridge located inside cluster C and connecting it to cluster B.

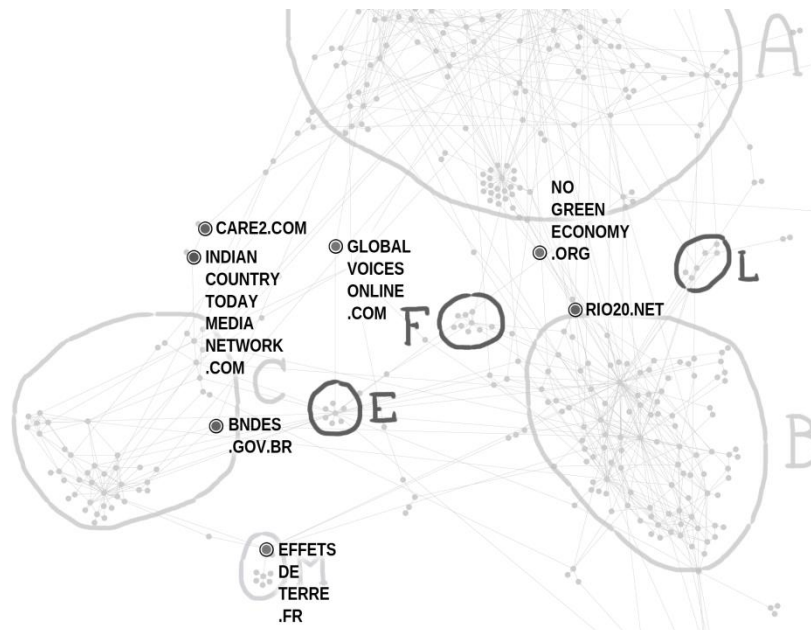

Figure 11 – Nodes and clusters in a bridging position

## INTERPRETATION

### Centers

**Nature.com** is the site of the famous scientific journal. It is an academic authority and is cited by all the many clusters, but not much (6 links in total). Of course, other websites exist that are cited by the nodes of the three main clusters (probably the major news websites), but they have not been included in the corpus because their content was not sufficiently focused on Rio +20 and its issues.

**UN.org** UN.org is a large portal linked to most of the numerous specialized institutions that constitute cluster B (and this explains its central position). The site contains static information on the United Nations: its mission, structure, Charter of Principles, the list of the member states and more. There is also a section of updates, daily news and highlighted dossiers.

**RealClimate.org** is a commentary website on climate science run by a group of renowned climate scientists and addressed to journalists and to the general public.

**CupolaDosPovos.org.br** is the center of the sub-cluster a4 “People’s Summit’ and its connections keep this star of nodes together. **IUCNWorldConservationCongress.org** and **Demilitarize.org** are in a similar position in clusters E and F.

## Bridges

Interestingly, in our network, the role of bridge is played not only by nodes but also by small clusters.

**Clusters E** “IUCN congress” is a bridge because of its focus on global warming mitigation. Mitigation is a key theme in conferences and events organized both by the institutions of the clusters B and the NGOs of the cluster C. As such it connects two distant regions of the network and facilitates their interaction.

Another site that promotes connections between clusters B “International Institutions” and C “Environmental and Climate NGOs” is the blog **Effets de Terre** (an independent version of the blog that the journalist Denis Delbecq maintained from 2005 to 2007 in the French newspaper Libération on climate change and environmentalism).

**Rio20.net** presents the program of the Cupola dos Povos event and is cited by several actors in clusters A and B. **NoGreenEconomy.org** is not an important website (the site seems “under construction” and it contains only 5 posts). Its position between A and B is explained by the fact that the website is maintained by a group of activists, whose position are close to those of the social movements in A while criticizing punctually the approach of the institutions in B (and thereby citing them).

For all other cases, we have found no convincing interpretation. When the bridging position of a node cannot be confirmed by the qualitative analysis of its content, the best option is simply to ignore it. Unlike the larger patterns visible in the networks, single edges are not always significant. The aim of the visual analysis of networks is not to explain the position of each and every node, but to detect large trends and notable nodes.

## VISUALIZING NODE SIZES

### HOW TO GIVE A SIZE TO NODES

We have now completed the part of the analysis based on the spatial position of nodes and we will start mobilizing the two other visual variables employed in the visual analysis of networks, starting from the size. In particular, we will now visualize the number of edges arriving to or leaving from a node by changing the diameter of the dot that represents it. We will first change the size of each node according to number of incoming links (the indegree) and then according to the number of outgoing links (the outdegree). To do so, we have used the ranking palette of Gephi and set the diameter to 1 for the smallest degree and 20 for the largest.

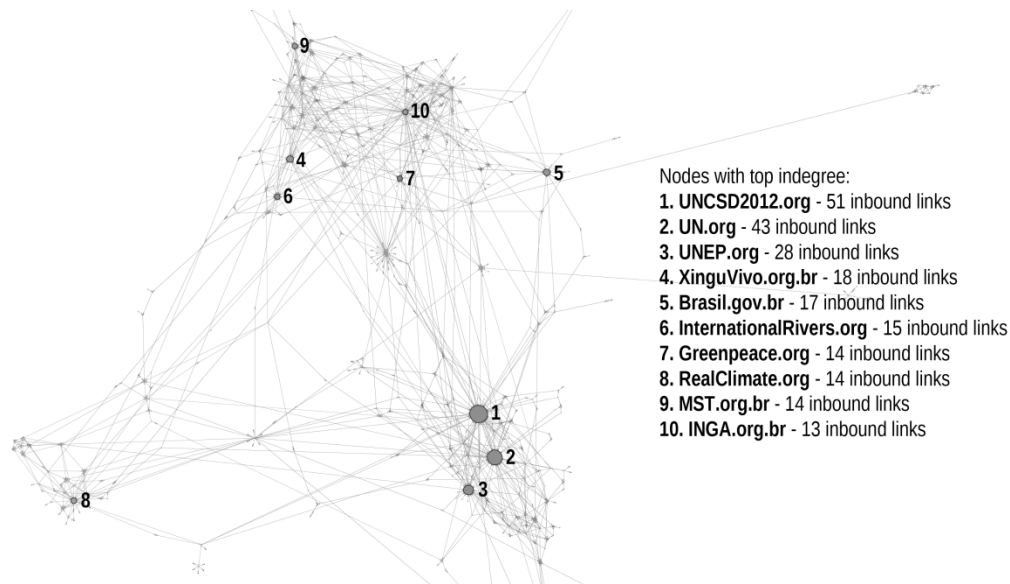

It is also possible (and indeed useful) to just look at the list of nodes sorted by their indegree or outdegree. Projecting the ranking on the spatialized networks, however, is also interesting as it allows identifying where the hubs and authorities are: are they central in a cluster or do they bridge different regions? Are they uniformly distributed or do they concentrate in some part of the graph? We could even go as far as to detect local hubs and authorities for each cluster (but we will not be so detailed in this article).

## HOW TO READ THE HIERARCHY OF CONNECTIVITY

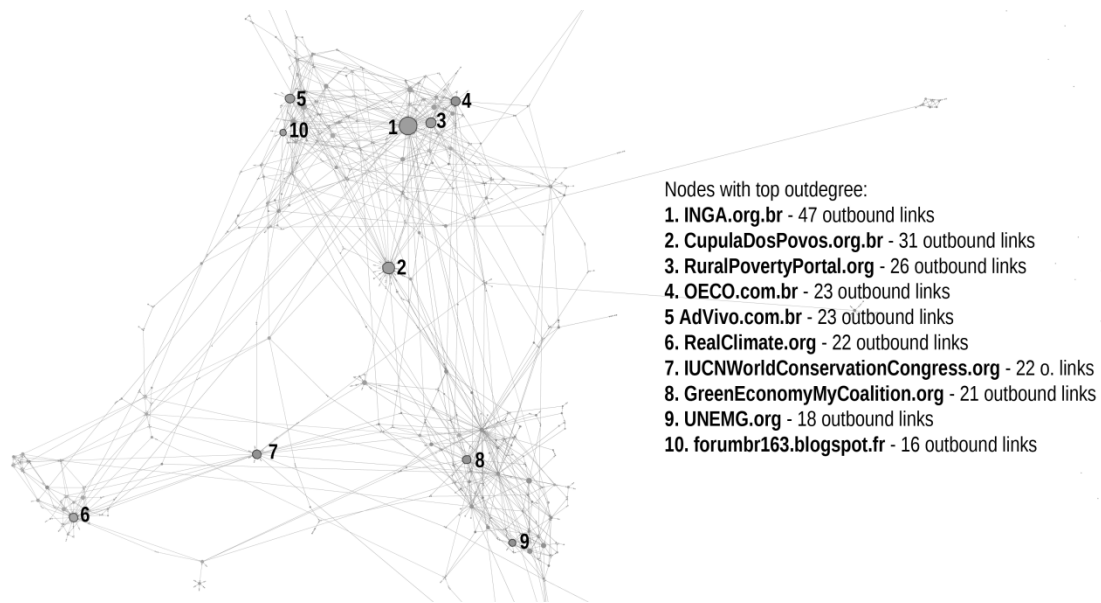

### *READING PRINCIPLE*

We will now consider the hierarchy of the most connected nodes. Following the tradition of network analysis, we will call “authorities” the nodes that are the destination of many edges and “hub” the nodes that are the origins of many edges. To put it simply, authorities are cited a lot while hubs cite a lot. Authorities are websites with a high visibility and toward which much of the traffic is addressed. Hubs are portals or websites that reference many other sites in the network. Both authorities and hubs tend to be influential nodes in the corpus.

Please remark that, in counting inbound and outbound links, we only take into consideration the connections within the corpus (and not all the hyperlinks that one website receives or sends). The website Nature.com for instance, is certainly an authority in the World Wide Web, but it is not in our smaller network (despite its very central position).

*Figure 12 – Top10 authorities: the ten most cited sites in the corpus [top indegree]*

*Figure 13 – Top10 hubs: the ten sites citing the most other sites in the corpus [top outdegree]*

### APPLICATION TO RIO+20

According to a power law often found in the Web (and in general in natural networks according to Barabasi, 2003), the distribution of the indegree is very skewed in this graph, with the three most cited websites having 28 to 51 inbound links, while the rest of the top10 varies from 18 to 13. It is remarkable that all three main authorities of the graph are located in cluster B “International Institutions”. The rest of the top10 (except for one authority in cluster C) is located in cluster A “NGOs and Social Movement”, whose high density of connection naturally produce local authorities.

As for the hubs, more than a half of the top10 (and the 5 biggest hubs) is located in the cluster A and again the density of such cluster can provide an explanation. It is interesting to remark the presence of an important hub “IUCN Congress” in a bridging position between B and C.

### *INTERPRETATION*

The main authorities of the network are all international institutions and this status seems to drive a large amount of hyperlinks to them. The three main authorities of the graph (uncsd2012.org, un.org and unep.org) are located in cluster B. The high density of this cluster and the lack of sub-clusters are largely due to the centripetal force of these three websites. These three websites are however local authorities: even if they receive links from other clusters, the largest part of their neighbors remains within cluster B.

Looking at outgoing links, given the high digital mobilization we observed in “NGOs and Social Movements”, it is not surprising that most hubs are in cluster A and that these sites correspond to very active communities: INGA.org.br, RuralPovertyPortal.org and OECO.com.br are strongly engaged on rural ecology; AdVivo.com.br and ForumBr163.blogspot.fr on Marxist questions.

## VISUALIZING NODE COLORS

### HOW TO APPLY A COLOR TO NODES

The last transformation we would like to operate on our network is to color its nodes according to the categories to which they belong. This stage, of course, is only possible if the nodes have been categorized beforehand. To be sure, the same nodes can and (when possible) should be classified according to different systems of classification. Each classification system is projected on the network as a layer of colors applied to the basemap. In our case, the nodes of the network had been categorized at the moment of the harvesting according to two different systems of classification: the approach to ecology that inspires them, and the language in which they are written. Drawing on these classifications, we can use the partition panel in Gephi to attribute a different hue to each type of nodes.

It is important to remind that the color is a non-mixable visual variable. A node can be red or blue but not the two at the same time. When categorizing nodes, it is therefore necessary to employ exclusive categories. A website, for example, should be categorized as French or English, but not as both. If both languages are present on the same websites, researchers can add an additional category 'multi-lingual' (which is also exclusive).

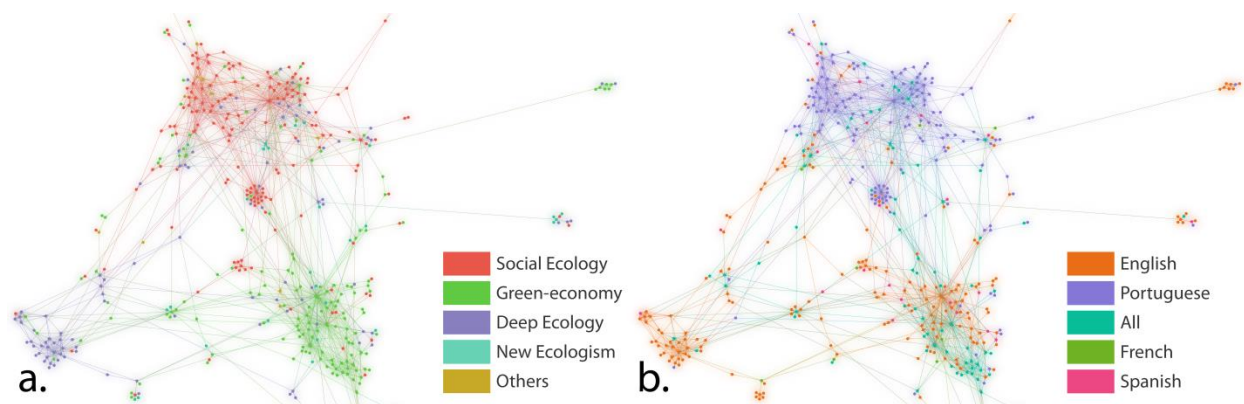

Figure 14 – Nodes of the network colored by approach (a) and language (b)

## HOW TO READ THE DISTRIBUTION OF COLORED CATEGORIES

### READING PRINCIPLE

Having colored the nodes of our graph, we can now examine how the colors are distributed in the different regions of the network. In particular, it is interesting to observe if the nodes of the same color tend to be closer than nodes of different colors – creating a correspondence between the typology and the topology of the network. When such correspondence is observed it can be used as a basis to explain the patterns observed in the network.

Of course, the correspondence between categories and clusters is not always bijective: one category does not always correspond to one cluster. One category may colonize more than one cluster and two or more categories can associate to form a single cluster. Still, if the nodes of the same color tend to be closer than others, there is ground for interpretation. An interesting example of this situation is provided by the so-called “hairball networks”. These are graphs that do not show any visible clusterization and are therefore difficult to analyze visually. However, when their nodes are colored, a polarization may appear. Even though the density of connection is homogeneous all over the graph, nodes of different categories may still be visually separated.

Finally, when different layers of classification are present in the network, it is interesting to compare them and observe whether the different classifications produce the same borders in the network. Often this is not the case and sometime this explains why the correspondence between categories and clusters is not bijective.

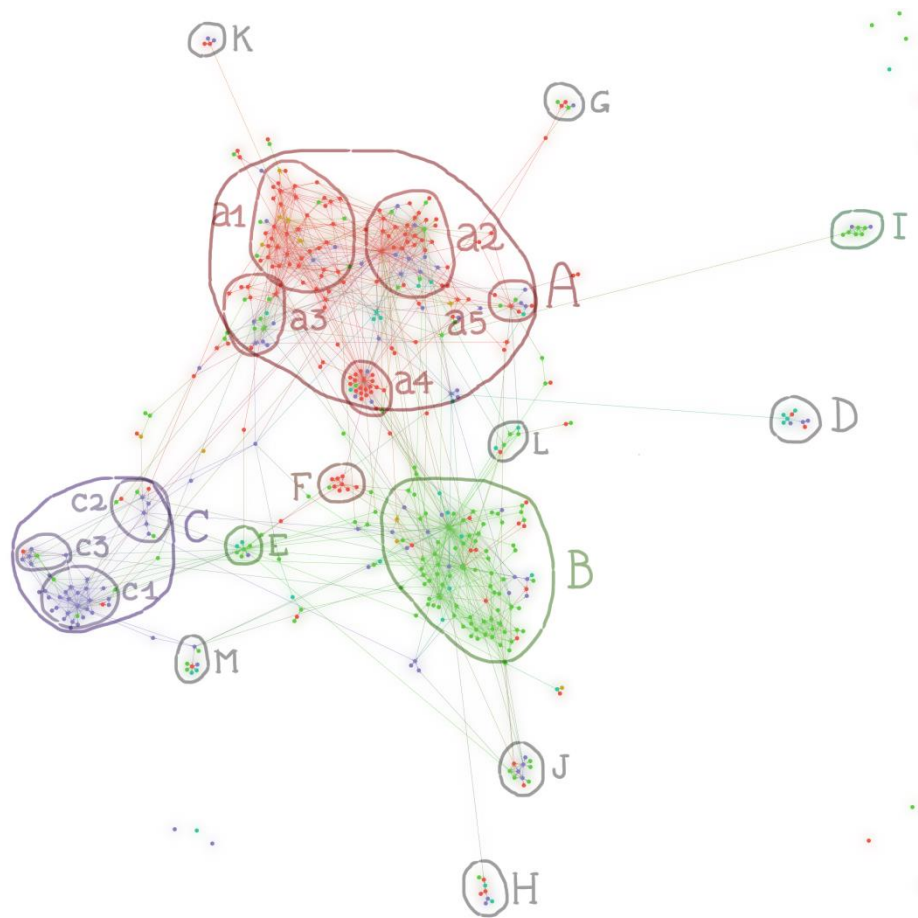

### APPLICATION TO RIO+20

The most interesting differences between the websites of our network concern their different approaches to ecology. In particular, it is possible to find in our corpus websites corresponding to the three main ‘schools’ described in the literature on ecology (Diegues, 2000; Koppes, 1989; Simonnet, 1979; Lipietz, 2012; Latour, 2004; Herber, 1964; Bramwell, 1989; Lynton, 1989; Lash Et Al, 1996; Zencey, 1989; Daly; Cobb, 1989):

- **Social Ecology:** explains environmental degradation as a result of capitalism and hierarchical division in society (between rich and poor, old and young, white, black and yellow). It advocates a return to primitive communitarian systems.
- **Deep Ecology:** deep ecology argues that nature was not given to humans, who have no right to use or exploit it. The objective of this type of ecology “is to preserve the nature of a hostile, essentially aggressive humanity” (Lipietz, 2012, p. 45).
- **New ecology:** emerged in the 60s, new ecology is directly opposed to consumerism.

An additional category, **Green Economy**, has been added to these to account for a large number of websites (32% of the corpus) that do not fit in any of the previous categories and seem to be unified by the fact of proposing a synergy between ecology and market economy. Finally, as always, there are cases that cannot be pigeonholed in any category and are therefore classified as “**Others**”.

Fig. 15 shows a clear correlation between our categorization and the topology of the network, as each of the three main clusters has a different dominant color. The cluster A “NGOs and Social Movements” is dominated by the social ecology approach; the cluster B “International Institutions” is dominated by the green ecology; and the cluster C “Environmental NGOs” by deep ecology. It is worth to remind that the spatialization algorithm we used does not take into consideration the categories of the nodes. The correspondence between hue and position is therefore a sign of strong correlation, so strong that we can make the hypothesis that the ideological agreement is a major driver of the connectivity in our network.

*Figure 15 – All main clusters have a distinctive color*

Coloring the websites according to their language (fig. 14b), we observe again a strong correspondence between typology and topology. Cluster A is largely composed by Portuguese websites, cluster B is divided between English and multilingual websites and cluster C is mostly in English. Since the proximity in the image indicates the (direct or indirect) connection, we observe a (not surprising) tendency to link websites of the same language.

It is interesting to observe the linguistic polarization of cluster B “International Institutions”, with English sites at the top and of multilingual sites at the bottom. Though clear-cut, the linguistic separation in the cluster is not strong enough to produce a structural hole separating two different sub-clusters.

It also interesting to remark that cluster C “Environmental NGOs” is also dominated by English websites and yet it does not merge to cluster B. Evidently, the organizational (NGOs vs. international institutions) and ideological differences (deep ecology VS green economy) are, in this case, stronger than the linguistic bound.

## *INTERPRETATION*

Drawing on the thematic and linguistic categorization, the separation between cluster A and B appears even deeper than we initially suspected. The two clusters are opposed by the type of organization that compose them (association VS institutions), by their approach to ecology (social ecology VS green economy) and by their language (Portuguese VS English and multilingual). This linguistic difference seems also to imply a different geographical focus (local VS global). In this sense it is interesting to remark that the English pole of cluster B is closer to A (more connected) than the multilingual pole.

On the other hand, the structural hole between B and C cannot be explained by language and derives probably from the different positions in the debate. We can also observe that while Portuguese websites cluster together, English websites do not. While Portuguese is the language shared by a community of local activists, English seems to be a neutral language used to address an international audience.

## CONCLUSIONS

In this paper we have presented basics of visual investigation of networks. This technique, we hope, will extend the “market” of network analysis, by making the power of networks available to scholars with limited mathematical knowledge. By translating the key notions of graph mathematics (clustering, authority, bridging...) into the three visual variables of position, size and hue, we have tried to provide scholars with methods to analyze medium sized and complex networks while sparing them most mathematical complications.

But there is more. Part of the interest of visual network analysis comes from the particular relationship between data and expertise that it proposes. Visual analysis entails a continuous iteration between observation of data and interpretation of findings. The continuous nature of two of the analytic variables (position and size) and the fact the third (color) depends on a manual categorization demand a constant engagement of the researcher’s choice. Where are the limits of each cluster? Which nodes are central or more visible? Which are the bridges? Spatialized and ranked networks may suggest insights, but they never impose answers to these questions.

This has advantages and drawbacks. The main disadvantage of visual analysis is that it is impossible without some previous knowledge of the data and the phenomenon that they refer to. Without the help of Debora, who has constructed the hyperlink network and has extensively studied Rio+20, there is no way we could have carried out such an insightful analysis. As every innovative research technique, visual research analysis is trapped in the “experimental regress” (Collins, 1975). Since both the method and its objects (the networks of hyperlinks, citations, words co-occurrence...) are still largely unexplored, it is hard to find a stable ground to establish their validity. How can we know that the patterns that we glimpse on the networks are not mere artifacts of the spatialization algorithm or projection of our previous knowledge? The only way out of these doubts is through the consistency between what we observe in the network and what we already know about the phenomenon it refers to. In our case, for example, we were comforted by finding a vast structural hole between social and deep ecology perfectly consistent with the long discussed difference between these two approaches. Also it was reassuring to

find the websites of the organizers of the event around which the corpus was built (uncsd2012.org, un.org and unep.org) as the three largest authorities of the networks.

Our visual analysis, however, did not just confirm what we already knew about Rio+20 (little interest would have otherwise). It also offered a few notable surprises. The importance and separation of the green economy cluster was one of them, as well as the centrality of CupulaDosPovos.org.br and the bridging position of the site of its alternative summit, Rio20.net. We have already discussed these and other findings in the article and we will not come back to them in the conclusion. These examples serve only to illustrate the main advantage of visual network analysis. Precisely because it provides insights and not clear-cut answers, the visual investigation of network is primarily a method for exploratory analysis (Tukey, 1977). By encouraging scholars to engage with their networks (sometime to struggle with them), visual network analysis forces researchers to assume an active attitude, to challenge and search ground for the previous knowledge and to open up to findings that they may not have thought to. Sometimes visual network is frowningly compared to “tasseography” (the art of interpreting patterns in tea leaves, coffee grounds, or wine sediments). To a certain extent this comparison is not amiss: not unlike the best forms of divination, visual analysis is indeed meant to confront enquirer to their data, to explore their networks, to question their ideas. In this paper, we hope we have provided some guideline for it.

# APPENDICE A: DESCRIPTION OF CLUSTERS

The **cluster A** gathers a series of websites by “**NGOs and social movements**”. Most of the actor represented are based in Brazil and are active in the protection of the environment and of the human rights. The contents of the websites include reports on the violence by the authorities; conflicts with the police; protest against the construction of dams and infrastructures; statements in favor of agro-ecology and environmental education. Each of the five sub-clusters of cluster A is characterized by a specific identity.

The **sub-cluster a1** is composed by the websites that are inspired by the theories of the **Marxist eco-socialism** (e.g. Via Campesina, Movimento dos Sem Terra, Movimento dos Atingidos por Barragens).

The **sub-cluster a2** features actors active in southern and central highlands of Brazil. It is more heterogeneous than a1, its members do not exhibit the same militant politics associated with Marxist ideology, but a softer version of **environmental politics**, which does not engage in politics and the struggle for human rights.

The **sub-cluster a3** is dominated by **Xingu Vivo movement** and shows a connection between local entities in the north and northeast of Brazil and transnational NGOs, such as International Rivers and Conservation Strategy. The principal struggle of the sites of this cluster is against the construction for dams in Xingu River.

The **sub-cluster a4** is dedicate to the **People's Summit**, an event in Rio de Janeiro organized by social movements in Brazil during the official United Nations Rio +20 summit, and aiming to be a protest against the official negotiations.

The **sub-cluster a5** is centered around the **official website of the Brazilian government**, referred to by the Institut National de la Recherche Agronomique in France, the government of Bogotá and the Forest Stewardship Council, which promotes the certification of forest management.

The **cluster B** is composed of “**international institutions**” related to the UN, and institutions that work with the concepts of green economy, sustainable development, green urban planning (critics may say that this cluster is mostly about the ‘green washing’ of modern society). The contents include reports on conferences and reports of debates and campaigns for citizen participation (including by digital means). Recurring themes are alternative energy, clean water, carbon market, biomaterials and green ICT. The cluster B is relatively homogeneous and does not exhibit any sub-clusters.

**Cluster C** consists of websites by “**environmental and climate NGOs**” for the preservation of nature, native movements (campaigns to buy land), and research groups defending the attribution of global warming to anthropic causes. The contents include several scientific articles. The visual appearance of the website is singular, with images of animals, forests, landscapes or nature, but without the presence of the man (often described as harmful to nature). We also note the presence of several appeals for donations. Cluster C is separated in three sub-clusters of different size and orientation.

The **sub-cluster c1** is composed of **scientific websites** debating about climate change. The most referenced sites are the Real Climate blog, EcoEquity, Skepticalscience, Climateaudit, and Simondonner Indigenize.

The **sub-cluster c2** is centered around **Mongabay**, an NGO whose main goal is to disseminate information and pictures about nature, and protesting against destruction."

The **sub-cluster c3** is formed of four websites (Forests, Rain Forests Portal, ClimateArk and Water Conservation) drawing contents from the **Ecological Internet**, a self-defining "non-profit organization that specializes in the use of the Internet to achieve conservation outcomes".
